15.6%.

The exact-match rate the first time I properly tested this.

Thirty messages, three runs each.

Six under-escalations. Ten missed safety signals.

It was calling real problems smaller than they were.

The obvious move is to tune the prompt until the number improves.

A number tuned against your own test set is a number about your test set.

What the failure actually said:

a model shouldn’t be the last thing standing between a gas smell and somebody’s phone.

So the life-safety decisions left the model.

A fixed layer runs afterward and checks the dangerous cases regardless of what the model concluded.

That layer can raise a priority. It has no path to ~~lower one.~~

- Gas
- flooding
- sewage
- fire
- sparking
- exposed wiring
- no heat
- no lock

It later passed a six-fixture gate with a clean sheet.

That gate is six messages I chose for a demo. The full thirty is still unfinished.

Which is why I don’t quote ~~an accuracy percentage~~ for this work, and

Ask a vendor what their number got wrong, and what changed because of it.
